1.1  \textit{N-Heterocyclic carbene (NHC)}

1.1.1 Historical perspective

Since the pioneering work of Doering in 1954, carbenes have been recognised as a unique type of intermediate with characteristics distinct from radicals already known in the organic chemistry community.\textsuperscript{1} Since then, research on carbenes has rapidly expanded, but almost no attempts were made to stabilise carbenes until the 1980s when Tomioka started to study persistent triplet diarylcarbenes.\textsuperscript{2}

The first isolable carbenes were reported in 1988 by Bertrand\textsuperscript{3} (1) and 1991 by Arduengo\textsuperscript{4} (2). Phosphinocarbene 1 can be distilled at 80-85°C/10^-2 Torr and \textit{N}-heterocyclic carbene (NHC) 2 is a crystalline solid that melts at above 240-241°C (Figure 1.1).

![Figure 1.1 The first isolated carbenes.](image)

Although NHCs have been known since the pioneering work of Wanzlick, who observed their dimerisation\textsuperscript{5} and was able to trap them to form mercury-salt carbene complexes,\textsuperscript{6} thirty years went by before the first NHC was isolated. The particular stability of the NHCs made them very popular and during the following years further analogues were synthesised (Figure 1.2).

In 1995, Arduengo proved\textsuperscript{7} using NHC 3 that aromaticity was not needed for stabilisation, and in 1996 Alder isolated acyclic NHC 4.\textsuperscript{8} This research area has been continually expanded with the isolation of four-membered carbene\textsuperscript{9} 5 by Grubbs and alkyl carbene\textsuperscript{10} 6 by Bertrand in 2004.

![Figure 1.2 Stable NHCs and their derivatives.](image)
1.1.2 Nomenclature

For the sake of homogeneity, the following nomenclature will be used throughout this work. NHCs which are related to an imidazoline structure will be called 1,3-di-R-imidazolin-2-ylidenes and NHCs with a saturated C-C double bond will be described as 1,3-di-R-imidazolidin-2-ylidenes (Figure 1.3).

![Nomenclature of the various NHCs.](image)

**Figure 1.3** Nomenclature of the various NHCs.

1.1.3 General characteristics

Carbenes are neutral divalent carbon with only six electrons in its valence shell. With two nitrogen substituents next to the C_carbene atom, the NHCs are predicted to stabilise their singlet state (two paired electrons in the σ orbital) by a push-pull effect (Figure 1.4). Firstly, the σ-electronwithdrawing nitrogen inductively stabilises the σ-nonbonding orbital by increasing its s-character. Secondly, the energy of the vacant p_σ-orbital is increased by interaction with the symmetric combination of the nitrogen lone pairs. Combination of the two effects increases the σ-p_σ gap and favours therefore the singlet state. Moreover, the pseudo sp^2 hybridisation adopted by the C_carbene atom in its singlet state matches the bent geometry of the NHC five-membered ring.

![Electronic stabilisation of NHCs.](image)

**Figure 1.4** Electronic stabilisation of NHCs.

The interaction of the nitrogen lone pair with the p_σ-orbital of the carbene is reflected by a N-C_carbene bond length of 1.365 Å, which is consistent with double bond character. An accurate assessment of the π backbonding was found by analysing dynamic ^1H-NMR behaviour of bis(diisopropylamine)carbene. As the major part of this process involves...
rotation about the N-C carbene bonds, the measured barrier to rotation of 53 kJ/mol was mostly attributed to the substantial π-component of these bonds.

Dimerisation of NHCs has been known since the first attempts to isolate them. Alder recently showed that dimerisation is thermodynamically unfavorable for imidazolin-2-ylidenes (singlet/triplet gap of 354 kJ/mol), but very likely to happen for imidazolidin-2-ylidenes due to lack of aromaticity and acyclic NHCs due to loss of conjugation through twisting around the N-C carbene bond. The reaction is likely to be proton catalysed.

The 13C-NMR chemical shifts range from 210-220 ppm downfield from TMS for aromatic imidazolin-2-ylidenes, to 235-245 ppm for imidazolidin-2-ylidenes and acyclic NHCs.

1.1.4 Generation of diaminocarbene / pKa

Three principal methods were successfully used for the generation of diaminocarbenes: i) deprotonation of imidazolium salts or formamidinium salts, ii) desulfurisation of thioureas and iii) thermolysis of methanol adducts of type (Figure 1.5).

![Figure 1.5](image)

The pKa value was measured for diisopropyl-imidazolin-2-ylidene on the DMSO scale and found to be 24 by Alder. For di-tert-butyl-imidazolin-2-ylidene Streitwieser found a pKa of 20 on the THF scale. Therefore, it is not surprising that the principal method used to synthesise NHCs is deprotonation of the corresponding imidazolium or formamidinium salts. For the isolation of the first NHC, Arduengo's group used NaH/KH in THF in the presence of KOtBu and DMSO (to generate the dimsyl ion). Herrmann showed that milder conditions...
such as sodium amide in liquid ammonia and THF at -40°C, were also efficient.\textsuperscript{18} With a pKa increased by 2 to 6 units, formamidinium salts underwent nucleophilic addition of the base rather than deprotonation.\textsuperscript{16} This problem was solved by the use of hindered alkali amide bases such as lithium diisopropylamide or potassium hexamethyldisilazide.

In 1993, Kuhn and Kratz reported another pathway to imidazolin-2-ylidene by reduction of the corresponding thiourea using metallic potassium.\textsuperscript{19} This heterogeneous reaction, which has proved difficult to reproduce,\textsuperscript{16} is attractive because the only other product is potassium sulfide which is insoluble in THF.

Finally, another successful method was established by Enders who synthesised in a good yield a triazol-2-ylidene by thermolysis of its methanol adduct.\textsuperscript{20} One drawback of this methodology is the extreme sensitivity of the methanol adduct.

### 1.2 N-Heterocyclic carbene metal complexes

#### 1.2.1 Historical perspective

Carbenes were introduced to inorganic chemistry by Fisher and Maasböl who reported that reaction of phenyl lithium with W(CO)\textsubscript{6}, followed by addition of acid and then diazomethane, gave complex 13 (Figure 1.6).\textsuperscript{21} A few years later Wanzlick and Öfele's first syntheses of NHC metal complexes respectively 14 and 15, extended the Fischer type carbene family.\textsuperscript{22,23}

In 1974, Schrock developed\textsuperscript{24} a new type of carbene, the so-called Schrock carbene, with a totally different reactivity (16).

\end{figure}

#### 1.2.2 NHC ligand properties

Although the metal carbene bond in Schrock and Fischer carbene complexes are both described as double bond, they differ by the polarity of the electron density. This difference
Introduction

arises from the difference in energy between the $d_\pi$ orbital of the metal and the $p_\pi$ orbital of the carbene (Figure 1.7). If the $d_\pi$ orbital is lower in energy than the $p_\pi$ orbital, the metal carbon bond is polarised $\delta^-$ on the metal and $\delta^+$ on the carbene and it is a Fischer carbene complex. Contrary, if the $d_\pi$ orbital is higher in energy than the $p_\pi$ orbital, the metal carbon bond is polarised $\delta^+$ on the metal and $\delta^-$ on the carbene and it is a Schrock carbene complex. A particular example of Fisher carbenes are NHCs which have a $p_\pi$ orbital of very high energy since their multiple bonding between the carbene atom and the two nitrogen atoms. As a result, the $p_\pi$ orbital does not interact well with the $d_\pi$, thus preventing almost any $\pi$-backbonding from the metal to the carbene. In the NHC complexes, the metal carbon bond is therefore best represented by a single bond.

**Figure 1.7** Partial molecular diagram for Schrock, Fischer and NHC carbene complexes.

The fundamental difference between a typical Schrock alkylidene moiety and an NHC as a ligand is underlined in the crystal structure of \([\text{RuCl}_2(\text{NHC})_2(=\text{CHC}_6\text{H}_4\text{Cl})]\) (NHC = 1,3-diisopropylimidazolin-2-ylidene) where the two types of carbenes are linked to the same metal centre.\(^{25}\) The ruthenium-carbon bond of the Schrock carbene, generally written as a double bond, has a bond length of 1.821(3) Å, whereas the Ru-C bond length to the NHC (2.107(3) Å and 2.115 (3)Å) justifies its representation as a single bond ($\sigma$-donor and virtually no $\pi$-acceptor).

Measurement of IR carbonyl absorption frequencies of NHC carbonyl metal (Fe, Cr, Rh, Mo and Ir) and their phosphine analogues showed the significantly increased donor capacity of NHC relative to phosphines, even to trialkylphosphines.\(^{26-28}\) Experimental investigations,\(^{29}\) calorimetric studies\(^{30,31}\) and experimental calculations\(^{32}\) agree that the ligand dissociation energy of NHCs from Ru complexes is higher than for phosphines. Further calculations with other metals such as Au, Cu, Ag, Pd and Pt led to similar conclusions.\(^{33,34}\)
By analogy to the cone angle defined for phosphines by Tolman, a method to quantify the steric parameters of NHCs has been proposed by Nolan who described NHCs as "fences" with "length" and "height". The structural differences for free NHCs and metal complexed NHCs are very small. In $^{13}$C-NMR spectra, the signals for the free carbene carbon are usually shifted upfield by about 20-30 ppm upon complexation of the free NHC to a transition metal.

1.2.3 Complexation

Four synthetic methodologies have been most commonly applied in the literature for the preparation of NHC metal complexes: i) proton abstraction with bases prior to metalation, ii) in situ deprotonation of the imidazolium by basic metalates or basic counter-ions, iii) use of an external base in a one pot reaction with the metal, and iv) transmetallation via silver complexes.

NHCs are very strong $\sigma$ donors and show dissociation energies higher than phosphines for a large range of metals (vide supra). Therefore, when their free form can be isolated, their complexation is achieved in high yield. It has been shown that free NHCs are able to cleave dimeric metallic species such as [$(\eta^4$-cod)RhCl)$_2$ and exchange phosphine or pyridine ligands.

In his original work, Öfele formed NHCs by in situ deprotonation of the corresponding imidazolium salts using the metal itself (Scheme 1.1). The basic metalate ion $[\text{HCr(CO)}_5\text{]}^-$ serves as base and ligand acceptors at the same time. One drawback of this method is the limited availability of the metal precursor.

\[ \text{Scheme 1.1 In situ deprotonation by a basic metalate ion} \]

Basic counter-ions of the metal precursors can also act as deprotonating agents. For example, a convenient method to synthesise NHC-Pd(II) complexes is by mixing Pd(OAc)$_2$ with the corresponding imidazolium salt. In a similar way, $\mu$-alkoxo complexes of $(\eta^4$-cod) rhodium(I) and iridium(I), formed in situ by adding $\mu$-chloro bridged analogues to a solution of sodium alkoxide in the corresponding alcohol, will deprotonate an imidazolium salt and deliver the corresponding NHC complex.
The use of an external base to generate NHCs in the presence of a metal precursor is also an efficient method. Potassium tert-butoxylate and sodium hydride in THF at room temperature can be used to co-ordinate NHCs to Cr(CO)₆ and to W(CO)₆ \textit{in situ}.³⁸ A large variety of bases ranging from triethylamine,³⁹ lithium diisopropylamide⁴⁰ to phosphazene bases⁴¹ have been successfully used over the past years.

Recently, a method for preparing NHC metal complex via silver complex has been developed by Wang.⁴² Silver NHC complexes are readily prepared upon mixing the corresponding imidazolium salt with Ag₂O in CH₂Cl₂ at room temperature. Subsequent reaction with a chloro-metal precursor gives the desired NHC metal complex that can be easily separated from AgCl, the latter being insoluble in THF.

1.2.4 Abnormal binding modes for NHC ligands

In 2001, Crabtree discovered an unexpected binding mode of NHCs. Instead of having co-ordination at the C(2) position of the NHC, the metal was linked at C(4) or C(5) (Figure 1.8).⁴³ Since this publication, there have been an increasing number of reports of NHC with abnormal binding mode.⁴⁴-⁴⁶

![Figure 1.8 C(2) and C(4) or C(5) binding mode of the NHCs.](image)

Non-classical carbene formation was initially observed by mixing pyridine-substituted imidazolium salts with [IrH₅(PPh₃)₂] in refluxing C₆H₆. Since theoretical calculation predicts⁴⁷ that binding at the C(4) or C(5) position is less favoured, it was reasoned that steric effects of the bidentate pyridine-NHC around the metal centre controlled the reaction. However, the isolation of monodentate NHC complexes with a C(4) or C(5) binding mode proved that the chemistry involved is more complicated than previously thought. Abnormal co-ordination of NHCs is still intensively studied.
1.3 Catalysis involving NHCs

1.3.1 Ruthenium metathesis

Due to their σ-donor ability and their strong metal-carbon bond, NHC ligands have been applied as directing ligands in various catalytic transformations. It is however in ruthenium-catalysed olefin metathesis type reactions that NHC ligands have proved their efficiency, giving access to unprecedented successful catalytic systems.

A breakthrough in catalytic metathesis reactions was achieved when NHC ligands were used to replace one of the phosphines of complex 17 (Figure 1.9). Herrmann showed that having one imidazolin-2-ylidene in place of a phosphine (18) favours the dissociative substitution of the phosphine ligand with an olefinic substrate, giving rise to a more active species. Catalysts 18 showed excellent activities in the ring opening metathesis of 1,5-cyclooctadiene.

In the same year, Grubbs introduced a new generation of ring closing metathesis catalysts containing an even more basic NHC. Catalyst 19, which contains an imidazolidin-2-ylidene ligand, showed outstanding activities combined with a large functional group tolerance. Moreover, the use of imidazolidin-2-ylidene allowed access to more chiral catalysts, by introduction of chirality at the C(4) and C(5) positions of the NHC. The application of complexes 20 in the desymmetrisation of triolefins yielded the ring closing metathesis products in high enantioselectivities.

![Figure 1.9 NHCs in ruthenium metathesis.]

1.3.2 Asymmetric catalysis

The first example of chiral carbenes used in asymmetric catalysis appeared in 1996/1997 with the pioneering work of Enders and Herrmann. Since then, the field has largely expanded and now there are many reports on the use of NHCs for asymmetric homogeneous catalysis. Enders successfully applied the NHC and their derivatives in carbene catalysed asymmetric
